*Can you see how the sticks (left side) are able to define the positions for the points (in the yellow box, right side) ?*

# The Distance Geometry Problem

Let  $G = (V, E, d)$  be a **simple weighted undirected graph**:

- $V$  represents a set of objects
- $E$  indicates which distances are known
- $d$  provides the “distance information”

## Definition

The **DGP** in dimension  $K$ .

Determine whether there exists a **realization**

$$x : V \longrightarrow \mathbb{R}^K$$

of  $G$  in  $\mathbb{R}^K$  such that, for all edges  $\{u, v\} \in E$ ,

$$\|x_u - x_v\| = d(u, v).$$

The **DGP** is NP-hard<sup>1</sup>.

<sup>1</sup>J. Saxe, Embeddability of Weighted Graphs in  $k$ -Space is Strongly NP-hard, Proceedings of 17<sup>th</sup> Allerton Conference in Communications, Control and Computing, 480–489, 1979.

The DGP is generally reformulated as a *continuous global optimization* problem:

$$\min g(X), \quad \text{where } g(X) = \sum_{\{u,v\}} (||x_u - x_v||^2 - d(u, v))^2$$

*The majority of available NMR models of protein conformations were obtained by solving the corresponding DGP by the meta-heuristic Simulated Annealing (SA).*

Some disadvantages:

- SA is **not** the best meta-heuristic search
- there are **no guarantees** to converge to the optimal solution(s)
- even with multi-start techniques, there is no hope to identify **all optimal solutions**

The chemical composition of a protein backbone:

**Exact** distances can be derived from the chemical composition of the molecule

**Interval** distances are obtained through the NMR experiments:

- mostly distances between *hydrogens*
- *short* distances ( $\leq 5\text{\AA}$ )
- *large range* for intervals (about  $2 - 3\text{\AA}$   $\Rightarrow$  uncertainty on the distance values)

The intersection of two circles in 2D gives (in general) two points.

## Definition

Given a **graph**  $G = (V, E, d)$ , there must exist<sup>2</sup> a **vertex order**<sup>3</sup> on  $V$  such that

**(A1)**  $G[\{1, 2, \dots, K\}]$  is a clique;

**(A2)**  $\forall v \in V : v > K, \exists u_1, u_2, \dots, u_K :$

$$\left\{ \begin{array}{l} u_1 < v, u_2 < v, \dots, u_K < v, \\ \{\{u_1, v\}, \{u_2, v\}, \dots, \{u_K, v\}\} \subset E, \\ \mathcal{V}(S[u_1, u_2, \dots, u_K]) \neq 0, \end{array} \right.$$

where  $S[\dots]$  is the simplex defined by  $u_1, u_2, \dots, u_K$ , and  $\mathcal{V}$  is the volume of its argument.

# A coarse-grained representation

We consider a **coarse-grained** representation of the search domain.

In such a case, a pair (position,box) is associated to a new node of the tree.

The *position* in the *box* can subsequently be refined by **local optimization**.<sup>5</sup>

But how to perform the local optimization step?

- spectral projected gradient
- Gauss-Newton second order method
- **Levenberg-Marquardt method**<sup>6</sup>

*Preliminary experiments are showing that the use of **local optimization** is very effective in correcting the **approximation errors** that can propagate along the search domain.*
